MAX40079/MAX40087/ MAX40077/MAX40089/ MAX40078

Single/Dual/Quad Ultra-Low Input Bias Current, Low Noise Amplifiers

General Description

The MAX40079/MAX40087/MAX40077/MAX40089/ MAX40078 are wide band, low-noise, low-input bias current operational amplifiers that offer rail-to-rail outputs and single-supply operation from 2.7V to 5.5V. These lownoise amps draw 2.2mA of quiescent supply current per amplifier. This family of amplifiers offers ultra-low distortion (0.0002% THD+N), as well as low input voltage-noise density $(4.2nV/\sqrt{Hz})$ and low input current-noise density (0.5fA/√Hz). The low input bias current of 0.3pA (typ) and low noise(4.5nV/√Hz), together with the wide bandwidth, provides excellent performance for transimpedance (TIA) and imaging applications.

These amplifiers have outputs which swing rail-to-rail and their input common-mode voltage range includes ground. The MAX40079/MAX40077/MAX40078 are single/dual/ quad respectively in unity-gain stable with a bandwidth of 10MHz. The MAX40087/MAX40089 are single/dual respectively with gain ≥ 5 stable and bandwidth of 42MHz. They operate over the full -40°C to +125°C temperature range.

Single channel op amps are available in 6-bump wafer-level package (WLP) and SOT23 6-pin packages. The dual channel op amps are available in 8-bump WLP and μMAX-8 packages. The quad channel option is available in 14-TSSOP package.

Applications

- Transimpedance Amplifiers
- pH Probes and Reference Electrodes
- **ADC Buffers**
- DAC Output Amplifiers
- Low-Noise Microphone/Preamplifiers
- **Digital Scales**
- **Strain Gauges/Sensor Amplifiers**
- **Medical Instrumentation**

[Ordering Information](#page-15-0) appears at end of data sheet.

Benefits and Features

- Low Input Voltage Noise Density: 4.2nV/√Hz at 30KHz
- Low Input Current Noise Density: 0.5fA/√Hz
- Low Input Bias Current: 0.3pA (typ)
- Low Distortion: 0.00035% or -109dB THD+N (1kΩ Load)
- Single-Supply Operation from +2.7V to +5.5V
- Input Common-Mode Voltage Range Includes Ground
- Rail-to-Rail Output Swings with a 1kΩ Load
- Wide Bandwidth: MAX40079/MAX40077/MAX40078 (10MHz); MAX40087/MAX40089 (42MHz)
- \bullet Excellent DC Characteristics: V_{OS} ≤ 70μV
- Single-Channel 6-bump WLP in 1.11mm x 0.76mm with 0.35mm Bump Pitch
- Dual-Channel 8-bump WLP in 0.96mm x 1.66mm with 0.35mm Bump Pitch
- Available in Space-Saving 6-WLP, 6-SOT, 8-WLP and μMAX Packages

Single/Dual/Quad Ultra-Low Input Bias Current, Low Noise Amplifiers

Detailed Description

The MAX40079/MAX40087/MAX40077/MAX40089/ MAX40078 single/dual/quad channel operational amplifiers feature ultra-low noise and distortion. Their low distortion and low noise make them ideal for use as pre-amplifiers in wide dynamic range applications, such as 16-bit analogto-digital converters. Their high input impedance and low noise are also useful for signal conditioning of high-impedance sources, such as piezoelectric transducers.

These devices have true rail-to-rail output operation, drive output resistive loads as low as 1kΩ while maintaining DC accuracy and can drive capacitive loads up to 200pF without any oscillation. The input common-mode voltage range extends from 0.2V below V_{SS} to (V_{DD} - 1.5V). The pushpull output stage maintains excellent DC characteristics, while delivering up to ± 20 mA of source/sink output current.

The MAX40079/MAX40079/MAX40078 are single/dual/ quad respectively that are unity-gain stable, while the MAX40087/MAX40089, single/dual respectively are decompensated version having higher slew rate and are stable for Gain ≥ 5V/V. The MAX40079/MAX40087 single channel op amps feature a low-power shutdown mode, which reduces the supply current to 0.1μA and places amplifiers outputs into a high impedance state.

Low Noise

The amplifiers input-referred voltage noise density is dominated by flicker noise(also known as 1/f noise) at lower frequencies and by thermal noise at higher frequencies. Overall thermal noise contribution is affected by the parallel combination of resistive feedback network $(R_F||R_G)$ depicted in [Figure 1](#page-11-0). These resistors should be reduced in cases where system bandwidth is large and thermal noise is dominant. Noise contribution factor can be reduced with increased gain settings.

For example, the input noise voltage density (e_N) of the circuit with R_F = 100kΩ, R_G = 10kΩ with Gain = 11V/V non-inverting configuration is $e_N = 12nV/\sqrt{Hz}$.

e_N can be reduced to 6nV/ \sqrt{Hz} by choosing R_F = 10kΩ, smaller R_G = 1kΩ compared to 10kΩ with still same Gain = 11V/V but at the expense of higher current consumption and higher distortion. Noise of this circuit is effectively reduced due to smaller value of R_G that dominates system noise.

Having a Gain of 101V/V with R_F = 100kΩ, R_G = 1kΩ, input referred voltage noise density is still a low 6nV/√Hz as the noise dominating resistor R_G remained the same.

Low Distortion

Many factors can affect the noise and distortion performance of the amplifier based on the design choices made. The following guidelines offer valuable information on the impact of design choices on total harmonic distortion (THD). Choosing correct feedback and gain resistor values for a particular application can be a very important factor in reducing THD. In general, the smaller the closedloop gain, the smaller the THD generated, especially when driving heavy resistive loads (in other words, smaller resistive load with higher output current). Operating the device near or above the full-power bandwidth significantly degrades distortion.

Referencing the load to either supply also improves the amplifier distortion performance, because only one of the MOSFETs of the push-pull output stage drives the output. Referencing the load to mid-supply increases the amplifier distortion for a given load and feedback setting (See the *Total Harmonic Distortion vs. Frequency* graph in the *[Typical Operating Characteristics](#page-5-0)*).

For gains ≥ 5 V/V, the de-compensated MAX40087/ MAX40089 deliver the best distortion performance as they have a higher slew rate and provide a higher amount of loop gain for a given closed-loop gain setting. Capacitive loads below 100pF do not significantly affect distortion results. Distortion performance is relatively constant over supply voltages.

Input Protection

As per **[Functional Diagram](#page-9-0)**, when voltage on either of the input pins goes up or below V_{DD} or V_{SS} by more than a diode voltage drop, ESD diodes begin to turn-on/forward bias and large amount of current flow through these diodes. If op amp inputs in certain applications are subject to these over-voltage conditions, insert a series current limiting 50 ohm resistors on either inputs. However, note that DC precision of the system be affected due to these series resistors and also thermal noise of these resistors need to be considered while making noise analysis of the entire circuit.

An input differential protection scheme is used (refer to **[Functional Diagram](#page-9-0)**) that protect the device if there is a large differential voltage applied across input pins. A series of 60Ω resistors are used in conjunction with a pair of back to back diodes that turn on in an event of differential voltage beyond a diode drop. A pair of 60Ω resistors limit current flowing through these diodes so that the current is limited below abs max rating of ±20mA.

Figure 1. Adding Feed-Forward Compensation

Since there is a differential protection scheme used in these family of op amps, these amplifiers cannot be used as comparators in open loop, which is often a possibility on an unused channel of op amp.

Using a Feed-Forward Compensation Capacitor, CZ

The amplifier's input capacitance is 7pF and if the resistance seen by the inverting input is large (**[Figure](#page-11-0) [1](#page-11-0)**) as a result of feedback network, this resistance and capacitance combination can introduce a pole within the amplifier's bandwidth resulting in reduced phase margin. Compensate the reduced phase margin by introducing a feed-forward capacitor (C_7) between the inverting input and the output (shown in **[Figure 1](#page-11-0)**). This effectively cancels the pole from the inverting input of the amplifier. Choose the value of C_Z as follows:

$$
C_Z = 10 \times (R_F/R_G) \,[pF]
$$

In the unity-gain stable: MAX40079/MAX40077/MAX40078, the use of correct value C_Z is most important for closed loop non-inverting gain $A_V = +2V/V$, and inverting gain A_V $= -1$ V/V.

In the de-compensated MAX40087/MAX40089, C_Z is most important for closed loop gain A_V = +10V/V.

Single/Dual/Quad Ultra-Low Input Bias Current, Low Noise Amplifiers

Using a slightly smaller $C₇$ than suggested by the formula above achieves a higher bandwidth at the expense of reduced phase and gain margin. As a general guideline, consider using C₇ for cases where $R_G||R_F$ is greater than 20kΩ (for MAX40079/MAX40077/MAX40078) and greater than 5kΩ (for MAX40087/MAX40089).

Applications Information

The MAX40079/MAX40087/MAX40077/MAX40089/ MAX40078 family of op amps combine good driving capability that can also support ground/low-side sensing input and rail-to-rail output operation. With their low distortion and low noise, they are ideal for use in ADC buffers, DAC output buffers, medical instrumentation systems and other noise-sensitive applications.

However, there are two main application areas where these ultra-low input bias current op amps find place and they are to measure high impedance measurements. High Impedance measurements can be interfacing either Current output sensors or voltage output sensors that would need very high output resistance to be interfaced with. These op amps offer just that as the input impedance of these amplifiers is in the range of **1000G**Ω.

Voltage output sensors readout can be accomplished with unity gain buffer configuration and current output sensors like photo-diodes current read out can be accomplished in transimpedance amplifier configuration discussed later in this data sheet.

Ground-Sensing and Rail-to-Rail Outputs

The common-mode input range of these devices extends below ground over temperature that offers excellent common mode rejection and can be used in low side current sensing applications. These devices are guaranteed not to undergo phase reversal when the input is overdriven over input common mode voltage range as shown in **[Figure 2](#page-12-0)**.

[Figure 3](#page-12-1) showcases the true rail-to-rail output operation of the amplifier, configured with $A_V = 5$ V/V. The output swings to within 8mV of the supplies with a 10kΩ load, making the devices ideal in low-supply voltage applications.

Figure 4. Photodiode Equivalent Circuit Showing Parasitics

Typical Application Circuit

Extremely Low-Leakage Op Amp (~50fA) Used as Transimpedance Amplifier

The ultra-low input bias current and low noise profile makes it an excellent choice for high impedance applications. It should be noted that unity gain stable is not a requirement for TIA applications. MAX40087/MAX40089 with increased GBW of 42MHz (min $Ay \ge 5V/V$) may also be an option.

[Figure 6](#page-13-0) shows a transimpedance amplifier using MAX40077 suited for low to moderate TIA applications in photo-voltaic mode with buffered reference. This enables negligible reverse-voltage across the photodiode which ensures little to no dark current. A typical bias point of 100mV–200mV may be used to ensure the output of amplifier to be in linear range. Because of the nature of photo-diode in photo-voltaic modes, the input capacitance is more as compared to photo-conductive mode. Therefore, this mode is chosen for slower to moderate photo-diode current applications but this methodology provides high linearity, better accuracy and low noise performance.

Photodiode Equivalent Circuit [\(Figure 4](#page-12-2)):

IP is current flowing through photodiode proportional to intensity of light on photodiode sensor

CJ is the junction input capacitance of the photodiode

 R_{SHUNT} is the internal shunt resistance of the photodiode

RSERIES is the internal series resistance of the photodiode where $V_{\text{OUT}} = I_P x R1$

where same equation still applies $V_{\text{OUT}} = I_P x R1$

The input capacitance of the diode can destabilize the amplifier when choosing R1 in such a way that $1/(2 \times \pi \times$ $R1 \times C_J$) < GBW of the op amp. A feedback capacitance

Figure 5. Single-Supply Transimpedance Amplifier Configuration **common-mode**
with Single-Channel Op Amp
vital Single-Channel Op Amp *with Single-Channel Op Amp*

Single/Dual/Quad Ultra-Low Input Bias Current, Low Noise Amplifiers

is required to add a zero to compensate for the phase shift. To learn more about Trans-impedance amplifier stabilization, please refer to the app note: AN5129: Stabilize your Transimpedance Amplifier.

For a critically damped system the f_{-3dB} =

 $\sqrt{\text{(GBW)}(2 \times \pi \times \text{R1} \times (\text{C1} + \text{CJ}))}$ and the value of C1

$$
= \sqrt{(CJ/2 \times \pi \times R1 \times GBW)}.
$$

When using MAX40087 de-compensated Op-Amp, care must be taken that the noise gain $(1 + C_J/C1)$ at higher frequencies is higher than gain of 5V/V in order to stabilize the TIA.

Noise Consideration: choosing lower R1 will provide lower transimpedance and higher BW, but this may result in higher noise as the signal reduces by a factor of R1 and noise reduces by factor of $\sqrt{R1}$.

The noise contribution of R1 can be reduced by increasing the C1 value, but this lowers the bandwidth. A careful trade-off must be done to improve the signal-to-noise ratio (SNR).

Output Buffering of an Un-Buffered DAC:

The **[Figure 7](#page-14-0)** shows the single MAX40079 configured as an output buffer for the MAX5541 16-bit DAC. Because the MAX5541 has an unbuffered voltage output, the input bias current of the op amp used must be less than 6nA to maintain 16-bit accuracy. This family of amplifiers have an input bias current of only 160pA (max) over temperature, virtually eliminating this as a source of error. In addition, the MAX40079 has excellent open loop gain and common-mode rejection, making this an excellent output

Figure 6. Single-Supply Transimpedance Amplifier Configuration with Dual-Channel Op Amp

Single/Dual/Quad Ultra-Low Input Bias Current, Low Noise Amplifiers

Figure 7. DAC Output Buffering with Op Amp

Capacitive Load Stability

The MAX40079 family of op amps drive up to 50pF in all configurations without any oscillation. Driving higher capacitive loads than 50pF might lead to oscillation in certain configurations due to reduction in phase margin and it can be seen as overshoot and undershoot with a step response on oscilloscope. If the application demands for the op amp to drive more than 50pF capacitive loads, it is recommended to add a series isolation resistor of 10-50 $Ω$ on the op amp output before capacitive load. Size of this resistor depends on the amount of capacitive load op amp is driving. Please refer to *Isolation Resistance vs. Capacitive Stability* graph in *[Typical Operating](#page-5-0) [Characteristics](#page-5-0)* for more information on resistance sizing.

This series isolation resistance is very useful in unity gain buffer configuration when full scale signal output swing is used as the unity gain configuration is the worst case for stability while driving capacitive loads.

Flux and Solder Contaminant Removal

Upon soldering process of the op amp on the PCB, remains of solder flux is a major performance degrading factor in measuring ultra-low input bias currents in the order of 50fA. Solvents like isopropyl alcohol (IPA) are effective in cleaning up solder flux contaminants. Upon clearly rubbing off the solder flux areas with IPA, ultrasonic cleaning in bath is highly recommended. Once the bath is completed, it can be dried up either at room temperature for several hours or placing the cleaned up PCB in an oven at elevated temperature for quick usage.

Power Supplies and Layout

The MAX40079/MAX40087/MAX40077/MAX40089/ MAX40078 op amps operate from a single +2.7V to +5.5V power supply or from dual supplies of ±1.35V to \pm 2.75V. For single-supply operation, bypass the V_{DD} power supply pin with a 0.1μF ceramic capacitor placed close to the V_{DD} pin. If operating from dual supplies, bypass both V_{DD} and V_{SS} supply pins with 0.1µF ceramic capacitor to ground. If additional decoupling is needed add another 4.7μF or 10μF where supply voltage is applied on PCB.

Good layout improves performance by decreasing the amount of stray capacitance and noise at the op amp inputs and output. To decrease stray capacitance, minimize PC board trace lengths and resistor leads, and place external components close to the op amp's pins.

Guard rings and Shielding is highly recommended to guard the high impedance input traces against input leakage current. Refer to MAX40077 EV kit data sheet for more information on this. This is accomplished using a Triax connector and drving it's guard to the same potential as the signal on high impedance input.
